Abstract

We develop fast algorithms for estimation of **generalized linear models with convex penalties**. The models include **linear regression**, **two-class logistic regression**, and **multinomial regression problems** while the penalties include ℓ_1 (the lasso), ℓ_2 (ridge regression) and mixtures of the two (the elastic net). The algorithms use **cyclical coordinate descent**, computed along **a regularization path**. The methods can handle large problems and can also deal efficiently with sparse features. In comparative timings we find that the new algorithms are considerably faster than competing methods.

Keywords: lasso, elastic net, logistic regression, ℓ_1 penalty, regularization path, coordinate-descent.

1. Introduction

The lasso (Tibshirani 1996) is a popular method for regression that uses an ℓ_1 penalty to achieve **a sparse solution**. In the signal processing literature, the lasso is also known as **basis pursuit** (Chen *et al.* 1998). This idea has been broadly applied, for example to generalized linear models (Tibshirani 1996) and Cox's proportional hazard models for survival data (Tibshirani 1997). In recent years, there has been an enormous amount of research activity devoted to related regularization methods:

1. The grouped lasso (Yuan and Lin 2007; Meier *et al.* 2008), where variables are included or excluded in groups.
2. The Dantzig selector (Candes and Tao 2007, and discussion), a slightly modified version of the lasso.
3. The *elastic net* (Zou and Hastie 2005) for correlated variables, which uses a penalty that is part ℓ_1 , part ℓ_2 .

4. ℓ_1 regularization paths for generalized linear models (Park and Hastie 2007a).
5. Methods using non-concave penalties, such as SCAD (Fan and Li 2005) and Friedman’s generalized elastic net (Friedman 2008), enforce more severe variable selection than the lasso.
6. Regularization paths for the support-vector machine (Hastie *et al.* 2004).
7. The graphical lasso (Friedman *et al.* 2008) for sparse covariance estimation and undirected graphs.

Efron *et al.* (2004) developed an efficient algorithm for computing the entire regularization path for the lasso for linear regression models. Their algorithm exploits the fact that the coefficient profiles are piecewise linear, which leads to an algorithm with the same computational cost as the full least-squares fit on the data (see also Osborne *et al.* 2000).

In some of the extensions above (items 2,3, and 6), piecewise-linearity can be exploited as in Efron *et al.* (2004) to yield efficient algorithms. Rosset and Zhu (2007) characterize the class of problems where piecewise-linearity exists—both the loss function and the penalty have to be quadratic or piecewise linear.

Here we instead focus on cyclical coordinate descent methods. These methods have been proposed for the lasso a number of times, but only recently was their power fully appreciated. Early references include Fu (1998), Shevade and Keerthi (2003) and Daubechies *et al.* (2004). Van der Kooij (2007) independently used coordinate descent for solving elastic-net penalized regression models. Recent rediscoveries include Friedman *et al.* (2007) and Wu and Lange (2008). The first paper recognized the value of solving the problem along an entire path of values for the regularization parameters, using the current estimates as warm starts. This strategy turns out to be remarkably efficient for this problem. Several other researchers have also re-discovered coordinate descent, many for solving the same problems we address in this paper—notably Shevade and Keerthi (2003), Krishnapuram and Hartemink (2005), Genkin *et al.* (2007) and Wu *et al.* (2009).

In this paper we extend the work of Friedman *et al.* (2007) and develop fast algorithms for fitting generalized linear models with elastic-net penalties. In particular, our models include regression, two-class logistic regression, and multinomial regression problems. Our algorithms can work on very large datasets, and can take advantage of sparsity in the feature set. We provide a publicly available package **glmnet** (Friedman *et al.* 2009) implemented in the R programming system (R Development Core Team 2009). We do not revisit the well-established convergence properties of coordinate descent in convex problems (Tseng 2001) in this article.

Lasso procedures are frequently used in domains with very large datasets, such as genomics and web analysis. Consequently a focus of our research has been algorithmic efficiency and speed. We demonstrate through simulations that our procedures outperform all competitors — even those based on coordinate descent.

In Section 2 we present the algorithm for the elastic net, which includes the lasso and ridge regression as special cases. Section 3 and 4 discuss (two-class) logistic regression and multinomial logistic regression. Comparative timings are presented in Section 5.

Although the title of this paper advertises regularization paths for GLMs, we only cover three important members of this family. However, exactly the same technology extends trivially to

other members of the exponential family, such as the Poisson model. We plan to extend our software to cover these important other cases, as well as the Cox model for survival data.

Note that this article is about **algorithms for fitting particular families of models, and not about the statistical properties of these models themselves.** Such discussions have taken place elsewhere.

2. Algorithms for the lasso, ridge regression and elastic net

We consider the usual setup for linear regression. We have a response variable $Y \in \mathbb{R}$ and a predictor vector $X \in \mathbb{R}^p$, and we approximate the regression function by a linear model $E(Y|X = x) = \beta_0 + x^\top \beta$. We have N observation pairs (x_i, y_i) . For simplicity we assume the x_{ij} are standardized: $\sum_{i=1}^N x_{ij} = 0$, $\frac{1}{N} \sum_{i=1}^N x_{ij}^2 = 1$, for $j = 1, \dots, p$. Our algorithms generalize naturally to the unstandardized case. The elastic net solves the following problem

$$\min_{(\beta_0, \beta) \in \mathbb{R}^{p+1}} R_\lambda(\beta_0, \beta) = \min_{(\beta_0, \beta) \in \mathbb{R}^{p+1}} \left[\frac{1}{2N} \sum_{i=1}^N (y_i - \beta_0 - x_i^\top \beta)^2 + \lambda P_\alpha(\beta) \right], \quad (1)$$

where

$$P_\alpha(\beta) = (1 - \alpha) \frac{1}{2} \|\beta\|_{\ell_2}^2 + \alpha \|\beta\|_{\ell_1} \quad (2)$$

$$= \sum_{j=1}^p \left[\frac{1}{2} (1 - \alpha) \beta_j^2 + \alpha |\beta_j| \right]. \quad (3)$$

P_α is the *elastic-net penalty* (Zou and Hastie 2005), and is a compromise between the ridge-regression penalty ($\alpha = 0$) and the lasso penalty ($\alpha = 1$). This penalty is particularly useful in the $p \gg N$ situation, or any situation where there are many correlated predictor variables.¹

Ridge regression is known to shrink the coefficients of correlated predictors towards each other, allowing them to borrow strength from each other. In the extreme case of k identical predictors, they each get identical coefficients with $1/k$ th the size that any single one would get if fit alone. From a Bayesian point of view, the ridge penalty is ideal if there are many predictors, and all have non-zero coefficients (drawn from a Gaussian distribution).

Lasso, on the other hand, is somewhat indifferent to very correlated predictors, and will tend to pick one and ignore the rest. In the extreme case above, the lasso problem breaks down. The lasso penalty corresponds to a Laplace prior, which expects many coefficients to be close to zero, and a small subset to be larger and nonzero.

The elastic net with $\alpha = 1 - \varepsilon$ for some small $\varepsilon > 0$ performs much like the lasso, but ~~removes any degeneracies and wild behavior caused by extreme correlations.~~ More generally, the entire family P_α creates a useful compromise between ridge and lasso. As α increases from 0 to 1, for a given λ the sparsity of the solution to (1) (i.e., the number of coefficients equal to zero) increases monotonically from 0 to the sparsity of the lasso solution.

Figure 1 shows an example that demonstrates the effect of varying α . The dataset is from (Golub et al. 1999), consisting of 72 observations on 3571 genes measured with DNA microarrays. The observations fall in two classes, so we use the penalties in conjunction with the

¹Zou and Hastie (2005) called this penalty the *naive* elastic net, and preferred a rescaled version which they called elastic net. We drop this distinction here.

Figure 1: Leukemia data: profiles of estimated coefficients for three methods, showing only first 10 steps (values for λ) in each case. For the elastic net, $\alpha = 0.2$.

logistic regression models of Section 3. The coefficient profiles from the first 10 steps (grid values for λ) for each of the three regularization methods are shown. The lasso penalty admits at most $N = 72$ genes into the model, while ridge regression gives all 3571 genes non-zero coefficients. The elastic-net penalty provides a compromise between these two, and has the effect of averaging genes that are highly correlated and then entering the averaged gene into the model. Using the algorithm described below, computation of the entire path of solutions for each method, at 100 values of the regularization parameter evenly spaced on the log-scale, took under a second in total. Because of the large number of non-zero coefficients for the ridge penalty, they are individually much smaller than the coefficients for the other methods. Consider a coordinate descent step for solving (1). That is, suppose we have estimates $\tilde{\beta}_0$ and $\tilde{\beta}_\ell$ for $\ell \neq j$, and we wish to partially optimize with respect to β_j . We would like to compute the gradient at $\beta_j = \tilde{\beta}_j$, which only exists if $\tilde{\beta}_j \neq 0$. If $\tilde{\beta}_j > 0$, then

$$\frac{\partial R_\lambda}{\partial \beta_j} \Big|_{\beta=\tilde{\beta}} = -\frac{1}{N} \sum_{i=1}^N x_{ij}(y_i - \tilde{\beta}_0 - x_i^\top \tilde{\beta}) + \lambda(1 - \alpha)\beta_j + \lambda\alpha. \quad (4)$$

A similar expression exists if $\tilde{\beta}_j < 0$, and $\tilde{\beta}_j = 0$ is treated separately. Simple calculus shows (Donoho and Johnstone 1994) that the coordinate-wise update has the form

$$\tilde{\beta}_j \leftarrow \frac{S\left(\frac{1}{N} \sum_{i=1}^N x_{ij}(y_i - \tilde{y}_i^{(j)}), \lambda\alpha\right)}{1 + \lambda(1 - \alpha)} \quad (5)$$

where

- $\tilde{y}_i^{(j)} = \tilde{\beta}_0 + \sum_{\ell \neq j} x_{i\ell} \tilde{\beta}_\ell$ is the fitted value excluding the contribution from x_{ij} , and hence $y_i - \tilde{y}_i^{(j)}$ the partial residual for fitting β_j . Because of the standardization, $\frac{1}{N} \sum_{i=1}^N x_{ij}(y_i - \tilde{y}_i^{(j)})$ is the simple least-squares coefficient when fitting this partial residual to x_{ij} .
- $S(z, \gamma)$ is the soft-thresholding operator with value

$$\text{sign}(z)(|z| - \gamma)_+ = \begin{cases} z - \gamma & \text{if } z > 0 \text{ and } \gamma < |z| \\ z + \gamma & \text{if } z < 0 \text{ and } \gamma < |z| \\ 0 & \text{if } \gamma \geq |z|. \end{cases} \quad (6)$$

The details of this derivation are spelled out in Friedman *et al.* (2007).

Thus we compute the simple least-squares coefficient on the partial residual, apply soft-thresholding to take care of the lasso contribution to the penalty, and then apply a proportional shrinkage for the ridge penalty. This algorithm was suggested by Van der Kooij (2007).

2.1. Naive updates

Looking more closely at (5), we see that

$$\begin{aligned} y_i - \tilde{y}_i^{(j)} &= y_i - \hat{y}_i + x_{ij} \tilde{\beta}_j \\ &= r_i + x_{ij} \tilde{\beta}_j, \end{aligned} \quad (7)$$

where \hat{y}_i is the current fit of the model for observation i , and hence r_i the current residual. Thus

$$\frac{1}{N} \sum_{i=1}^N x_{ij}(y_i - \tilde{y}_i^{(j)}) = \frac{1}{N} \sum_{i=1}^N x_{ij}r_i + \tilde{\beta}_j, \quad (8)$$

because the x_j are standardized. The first term on the right-hand side is the gradient of the loss with respect to β_j . It is clear from (8) why coordinate descent is computationally efficient. Many coefficients are zero, remain zero after the thresholding, and so nothing needs to be changed. Such a step costs $O(N)$ operations—the sum to compute the gradient. On the other hand, if a coefficient does change after the thresholding, r_i is changed in $O(N)$ and the step costs $O(2N)$. Thus a complete cycle through all p variables costs $O(pN)$ operations. We refer to this as the *naive algorithm*, since it is generally less efficient than the *covariance updating* algorithm to follow. Later we use these algorithms in the context of iteratively reweighted least squares (IRLS), where the observation weights change frequently; there the naive algorithm dominates.

2.2. Covariance updates

Further efficiencies can be achieved in computing the updates in (8). We can write the first term on the right (up to a factor $1/N$) as

$$\sum_{i=1}^N x_{ij}r_i = \langle x_j, y \rangle - \sum_{k: |\tilde{\beta}_k| > 0} \langle x_j, x_k \rangle \tilde{\beta}_k, \quad (9)$$

where $\langle x_j, y \rangle = \sum_{i=1}^N x_{ij}y_i$. Hence we need to compute inner products of each feature with y initially, and then each time a new feature x_k enters the model (for the first time), we need to compute and store its inner product with all the rest of the features ($O(Np)$ operations). We also store the p gradient components (9). If one of the coefficients currently in the model changes, we can update each gradient in $O(p)$ operations. Hence with m non-zero terms in the model, a complete cycle costs $O(pm)$ operations if no new variables become non-zero, and costs $O(Np)$ for each new variable entered. Importantly, $O(N)$ calculations do not have to be made at every step. This is the case for all penalized procedures with squared error loss.

2.3. Sparse updates

We are sometimes faced with problems where the $N \times p$ feature matrix \mathbf{X} is extremely sparse. A leading example is from document classification, where the feature vector uses the so-called “bag-of-words” model. Each document is scored for the presence/absence of each of the words in the entire dictionary under consideration (sometimes counts are used, or some transformation of counts). Since most words are absent, the feature vector for each document is mostly zero, and so the entire matrix is mostly zero. We store such matrices efficiently in *sparse column format*, where we store only the non-zero entries and the coordinates where they occur.

Coordinate descent is ideally set up to exploit such sparsity, in an obvious way. The $O(N)$ inner-product operations in either the naive or covariance updates can exploit the sparsity, by summing over only the non-zero entries. Note that in this case scaling of the variables will

not alter the sparsity, but centering will. So scaling is performed up front, but the centering is incorporated in the algorithm in an efficient and obvious manner.

2.4. Weighted updates

Often a weight w_i (other than $1/N$) is associated with each observation. This will arise naturally in later sections where observations receive weights in the IRLS algorithm. In this case the update step (5) becomes only slightly more complicated:

$$\tilde{\beta}_j \leftarrow \frac{S\left(\sum_{i=1}^N w_i x_{ij}(y_i - \tilde{y}_i^{(j)}), \lambda\alpha\right)}{\sum_{i=1}^N w_i x_{ij}^2 + \lambda(1 - \alpha)}. \quad (10)$$

If the x_j are not standardized, there is a similar sum-of-squares term in the denominator (even without weights). The presence of weights does not change the computational costs of either algorithm much, as long as the weights remain fixed.

2.5. Pathwise coordinate descent

We compute the solutions for a decreasing sequence of values for λ , starting at the smallest value λ_{\max} for which the entire vector $\tilde{\beta} = 0$. Apart from giving us a path of solutions, this scheme exploits *warm starts*, and leads to a more stable algorithm. We have examples where it is faster to compute the path down to λ (for small λ) than the solution only at that value for λ .

When $\tilde{\beta} = 0$, we see from (5) that $\tilde{\beta}_j$ will stay zero if $\frac{1}{N}|\langle x_j, y \rangle| < \lambda\alpha$. Hence $N\alpha\lambda_{\max} = \max_{\ell} |\langle x_{\ell}, y \rangle|$. Our strategy is to select a minimum value $\lambda_{\min} = \epsilon\lambda_{\max}$, and construct a sequence of K values of λ decreasing from λ_{\max} to λ_{\min} on the log scale. Typical values are $\epsilon = 0.001$ and $K = 100$.

2.6. Other details

Irrespective of whether the variables are standardized to have variance 1, we always center each predictor variable. Since the intercept is not regularized, this means that $\hat{\beta}_0 = \bar{y}$, the mean of the y_i , for all values of α and λ .

It is easy to allow different penalties λ_j for each of the variables. We implement this via a penalty scaling parameter $\gamma_j \geq 0$. If $\gamma_j > 0$, then the penalty applied to β_j is $\lambda_j = \lambda\gamma_j$. If $\gamma_j = 0$, that variable does not get penalized, and always enters the model unrestricted at the first step and remains in the model. Penalty rescaling would also allow, for example, our software to be used to implement the *adaptive lasso* (Zou 2006).

Considerable speedup is obtained by organizing the iterations around the *active set* of features—those with nonzero coefficients. After a complete cycle through all the variables, we iterate on only the active set till convergence. If another complete cycle does not change the active set, we are done, otherwise the process is repeated. Active-set convergence is also mentioned in Meier *et al.* (2008) and Krishnapuram and Hartemink (2005).

3. Regularized logistic regression

When the response variable is binary, the linear logistic regression model is often used. Denote by G the response variable, taking values in $\mathcal{G} = \{1, 2\}$ (the labeling of the elements is arbitrary). The logistic regression model represents **the class-conditional probabilities through a linear function of the predictors**

$$\begin{aligned}\Pr(G = 1|x) &= \frac{1}{1 + e^{-(\beta_0 + x^\top \beta)}}, \\ \Pr(G = 2|x) &= \frac{1}{1 + e^{+(\beta_0 + x^\top \beta)}} \\ &= 1 - \Pr(G = 1|x).\end{aligned}\tag{11}$$

Alternatively, this implies that

$$\log \frac{\Pr(G = 1|x)}{\Pr(G = 2|x)} = \beta_0 + x^\top \beta.\tag{12}$$

Here we fit this model **by regularized maximum (binomial) likelihood**. Let $p(x_i) = \Pr(G = 1|x_i)$ be the probability (11) for observation i at a particular value for the parameters (β_0, β) , then we **maximize the penalized log likelihood**

$$\max_{(\beta_0, \beta) \in \mathbb{R}^{p+1}} \left[\frac{1}{N} \sum_{i=1}^N \{I(g_i = 1) \log p(x_i) + I(g_i = 2) \log(1 - p(x_i))\} - \lambda P_\alpha(\beta) \right].\tag{13}$$

Denoting $y_i = I(g_i = 1)$, the log-likelihood part of (13) can be written in the more explicit form

$$\ell(\beta_0, \beta) = \frac{1}{N} \sum_{i=1}^N y_i \cdot (\beta_0 + x_i^\top \beta) - \log(1 + e^{(\beta_0 + x_i^\top \beta)}),\tag{14}$$

a concave function of the parameters. The Newton algorithm for maximizing the (unpenalized) log-likelihood (14) amounts to iteratively reweighted least squares. Hence if the current estimates of the parameters are $(\tilde{\beta}_0, \tilde{\beta})$, we form a quadratic approximation to the log-likelihood (Taylor expansion about current estimates), which is

$$\ell_Q(\beta_0, \beta) = -\frac{1}{2N} \sum_{i=1}^N w_i (z_i - \beta_0 - x_i^\top \beta)^2 + C(\tilde{\beta}_0, \tilde{\beta})^2\tag{15}$$

where

$$z_i = \tilde{\beta}_0 + x_i^\top \tilde{\beta} + \frac{y_i - \tilde{p}(x_i)}{\tilde{p}(x_i)(1 - \tilde{p}(x_i))}, \quad (\text{working response})\tag{16}$$

$$w_i = \tilde{p}(x_i)(1 - \tilde{p}(x_i)), \quad (\text{weights})\tag{17}$$

and $\tilde{p}(x_i)$ is evaluated at the current parameters. The last term is constant. The Newton update is obtained by minimizing ℓ_Q .

Our approach is similar. For each value of λ , we create an outer loop which computes the quadratic approximation ℓ_Q about the current parameters $(\tilde{\beta}_0, \tilde{\beta})$. Then we use coordinate descent to solve the penalized weighted least-squares problem

$$\min_{(\beta_0, \beta) \in \mathbb{R}^{p+1}} \{-\ell_Q(\beta_0, \beta) + \lambda P_\alpha(\beta)\}.\tag{18}$$

This amounts to a sequence of nested loops:

outer loop: Decrement λ .

middle loop: Update the quadratic approximation ℓ_Q using the current parameters $(\tilde{\beta}_0, \tilde{\beta})$.

inner loop: Run the coordinate descent algorithm on the penalized weighted-least-squares problem (18).

There are several important details in the implementation of this algorithm.

- When $p \gg N$, one cannot run λ all the way to zero, because the saturated logistic regression fit is undefined (parameters wander off to $\pm\infty$ in order to achieve probabilities of 0 or 1). Hence the default λ sequence runs down to $\lambda_{\min} = \epsilon\lambda_{\max} > 0$.
- Care is taken to avoid coefficients diverging in order to achieve fitted probabilities of 0 or 1. When a probability is within $\epsilon = 10^{-5}$ of 1, we set it to 1, and set the weights to ϵ . 0 is treated similarly.
- Our code has an option to approximate the Hessian terms by an exact upper-bound. This is obtained by setting the w_i in (17) all equal to 0.25 (Krishnapuram and Hartemink 2005).
- We allow the response data to be supplied in the form of a two-column matrix of counts, sometimes referred to as *grouped* data. We discuss this in more detail in Section 4.2.
- The Newton algorithm is not guaranteed to converge without step-size optimization (Lee et al. 2006). Our code does not implement any checks for divergence; this would slow it down, and when used as recommended we do not feel it is necessary. We have a closed form expression for the starting solutions, and each subsequent solution is warm-started from the previous close-by solution, which generally makes the quadratic approximations very accurate. We have not encountered any divergence problems so far.

4. Regularized multinomial regression

When the categorical response variable G has $K > 2$ levels, the linear logistic regression model can be generalized to a multi-logit model. The traditional approach is to extend (12) to $K - 1$ logits

$$\log \frac{\Pr(G = \ell|x)}{\Pr(G = K|x)} = \beta_{0\ell} + x^\top \beta_\ell, \ell = 1, \dots, K - 1. \quad (19)$$

Here β_ℓ is a p -vector of coefficients. As in Zhu and Hastie (2004), here we choose a more symmetric approach. We model

$$\Pr(G = \ell|x) = \frac{e^{\beta_{0\ell} + x^\top \beta_\ell}}{\sum_{k=1}^K e^{\beta_{0k} + x^\top \beta_k}} \quad (20)$$

This parametrization is not estimable without constraints, because for any values for the parameters $\{\beta_{0\ell}, \beta_\ell\}_1^K$, $\{\beta_{0\ell} - c_0, \beta_\ell - c\}_1^K$ give identical probabilities (20). Regularization deals with this ambiguity in a natural way; see Section 4.1 below.

We fit the model (20) by regularized maximum (multinomial) likelihood. Using a similar notation as before, let $p_\ell(x_i) = \Pr(G = \ell | x_i)$, and let $g_i \in \{1, 2, \dots, K\}$ be the i th response. We maximize the penalized log-likelihood

$$\max_{\{\beta_{0\ell}, \beta_\ell\}_1^K \in \mathbb{R}^{K(p+1)}} \left[\frac{1}{N} \sum_{i=1}^N \log p_{g_i}(x_i) - \lambda \sum_{\ell=1}^K P_\alpha(\beta_\ell) \right]. \quad (21)$$

Denote by \mathbf{Y} the $N \times K$ *indicator* response matrix, with elements $y_{i\ell} = I(g_i = \ell)$. Then we can write the log-likelihood part of (21) in the more explicit form

$$\ell(\{\beta_{0\ell}, \beta_\ell\}_1^K) = \frac{1}{N} \sum_{i=1}^N \left[\sum_{\ell=1}^K y_{i\ell} (\beta_{0\ell} + x_i^\top \beta_\ell) - \log \left(\sum_{\ell=1}^K e^{\beta_{0\ell} + x_i^\top \beta_\ell} \right) \right]. \quad (22)$$

The Newton algorithm for multinomial regression can be tedious, because of the vector nature of the response observations. Instead of weights w_i as in (17), we get weight *matrices*, for example. However, in the spirit of coordinate descent, we can avoid these complexities. We perform *partial Newton steps* by forming a partial quadratic approximation to the log-likelihood (22), allowing only $(\beta_{0\ell}, \beta_\ell)$ to vary for a single class at a time. It is not hard to show that this is

$$\ell_{Q\ell}(\beta_{0\ell}, \beta_\ell) = -\frac{1}{2N} \sum_{i=1}^N w_{i\ell} (z_{i\ell} - \beta_{0\ell} - x_i^\top \beta_\ell)^2 + C(\{\tilde{\beta}_{0k}, \tilde{\beta}_k\}_1^K), \quad (23)$$

where as before

$$z_{i\ell} = \tilde{\beta}_{0\ell} + x_i^\top \tilde{\beta}_\ell + \frac{y_{i\ell} - \tilde{p}_\ell(x_i)}{\tilde{p}_\ell(x_i)(1 - \tilde{p}_\ell(x_i))}, \quad (24)$$

$$w_{i\ell} = \tilde{p}_\ell(x_i)(1 - \tilde{p}_\ell(x_i)), \quad (25)$$

Our approach is similar to the two-class case, except now we have to cycle over the classes as well in the outer loop. For each value of λ , we create an outer loop which cycles over ℓ and computes the partial quadratic approximation $\ell_{Q\ell}$ about the current parameters $(\tilde{\beta}_0, \tilde{\beta})$. Then we use coordinate descent to solve the penalized weighted least-squares problem

$$\min_{(\beta_{0\ell}, \beta_\ell) \in \mathbb{R}^{p+1}} \{-\ell_{Q\ell}(\beta_{0\ell}, \beta_\ell) + \lambda P_\alpha(\beta_\ell)\}. \quad (26)$$

This amounts to the sequence of nested loops:

outer loop: Decrement λ .

middle loop (outer): Cycle over $\ell \in \{1, 2, \dots, K, 1, 2, \dots\}$.

middle loop (inner): Update the quadratic approximation $\ell_{Q\ell}$ using the current parameters $\{\tilde{\beta}_{0k}, \tilde{\beta}_k\}_1^K$.

inner loop: Run the co-ordinate descent algorithm on the penalized weighted-least-squares problem (26).

4.1. Regularization and parameter ambiguity

As was pointed out earlier, if $\{\beta_{0\ell}, \beta_{\ell}\}_1^K$ characterizes a fitted model for (20), then $\{\beta_{0\ell} - c_0, \beta_{\ell} - c\}_1^K$ gives an identical fit (c is a p -vector). Although this means that the log-likelihood part of (21) is insensitive to (c_0, c) , the penalty is not. In particular, we can always improve an estimate $\{\beta_{0\ell}, \beta_{\ell}\}_1^K$ (w.r.t. (21)) by solving

$$\min_{c \in \mathbb{R}^p} \sum_{\ell=1}^K P_{\alpha}(\beta_{\ell} - c). \quad (27)$$

This can be done separately for each coordinate, hence

$$c_j = \arg \min_t \sum_{\ell=1}^K \left[\frac{1}{2}(1 - \alpha)(\beta_{j\ell} - t)^2 + \alpha|\beta_{j\ell} - t| \right]. \quad (28)$$

Theorem 1 Consider problem (28) for values $\alpha \in [0, 1]$. Let $\bar{\beta}_j$ be the mean of the $\beta_{j\ell}$, and β_j^M a median of the $\beta_{j\ell}$ (and for simplicity assume $\bar{\beta}_j \leq \beta_j^M$). Then we have

$$c_j \in [\bar{\beta}_j, \beta_j^M], \quad (29)$$

with the left endpoint achieved if $\alpha = 0$, and the right if $\alpha = 1$.

The two endpoints are obvious. The proof of Theorem 1 is given in Appendix A. A consequence of the theorem is that a very simple search algorithm can be used to solve (28). The objective is piecewise quadratic, with knots defined by the $\beta_{j\ell}$. We need only evaluate solutions in the intervals including the mean and median, and those in between. We *recenter* the parameters in each index set j after each *inner middle loop* step, using the the solution c_j for each j .

Not all the parameters in our model are regularized. The intercepts $\beta_{0\ell}$ are not, and with our penalty modifiers γ_j (Section 2.6) others need not be as well. For these parameters we use mean centering.

4.2. Grouped and matrix responses

As in the two class case, the data can be presented in the form of a $N \times K$ matrix $m_{i\ell}$ of non-negative numbers. For example, if the data are grouped: at each x_i we have a number of multinomial samples, with $m_{i\ell}$ falling into category ℓ . In this case we divide each row by the row-sum $m_i = \sum_{\ell} m_{i\ell}$, and produce our response matrix $y_{i\ell} = m_{i\ell}/m_i$. m_i becomes an observation weight. Our penalized maximum likelihood algorithm changes in a trivial way. The working response (24) is defined exactly the same way (using $y_{i\ell}$ just defined). The weights in (25) get augmented with the observation weight m_i :

$$w_{i\ell} = m_i \tilde{p}_{\ell}(x_i)(1 - \tilde{p}_{\ell}(x_i)). \quad (30)$$

Equivalently, the data can be presented directly as a matrix of class proportions, along with a weight vector. From the point of view of the algorithm, any matrix of positive numbers and any non-negative weight vector will be treated in the same way.

5. Timings

In this section we compare the run times of the coordinate-wise algorithm to some competing algorithms. These use the lasso penalty ($\alpha = 1$) in both the regression and logistic regression settings. All timings were carried out on an Intel Xeon 2.80GH processor.

We do not perform comparisons on the elastic net versions of the penalties, since there is not much software available for elastic net. Comparisons of our **glmnet** code with the R package **elasticnet** will mimic the comparisons with **lars** (Hastie and Efron 2007) for the lasso, since **elasticnet** (Zou and Hastie 2004) is built on the **lars** package.

5.1. Regression with the lasso

We generated Gaussian data with N observations and p predictors, with each pair of predictors $X_j, X_{j'}$ having the same population correlation ρ . We tried a number of combinations of N and p , with ρ varying from zero to 0.95. The outcome values were generated by

$$Y = \sum_{j=1}^p X_j \beta_j + k \cdot Z \quad (31)$$

where $\beta_j = (-1)^j \exp(-2(j-1)/20)$, $Z \sim N(0, 1)$ and k is chosen so that the signal-to-noise ratio is 3.0. The coefficients are constructed to have alternating signs and to be exponentially decreasing.

Table 1 shows the average CPU timings for the coordinate-wise algorithm, and the **lars** procedure (Efron *et al.* 2004). All algorithms are implemented as R functions. The coordinate-wise algorithm does all of its numerical work in Fortran, while **lars** (Hastie and Efron 2007) does much of its work in R, calling Fortran routines for some matrix operations. However comparisons in Friedman *et al.* (2007) showed that **lars** was actually faster than a version coded entirely in Fortran. Comparisons between different programs are always tricky: in particular the **lars** procedure computes the entire path of solutions, while the coordinate-wise procedure solves the problem for a set of pre-defined points along the solution path. In the orthogonal case, **lars** takes $\min(N, p)$ steps: hence to make things roughly comparable, we called the latter two algorithms to solve a total of $\min(N, p)$ problems along the path. Table 1 shows timings in seconds averaged over three runs. We see that **glmnet** is considerably faster than **lars**; the covariance-updating version of the algorithm is a little faster than the naive version when $N > p$ and a little slower when $p > N$. We had expected that high correlation between the features would increase the run time of **glmnet**, but this does not seem to be the case.

5.2. Lasso-logistic regression

We used the same simulation setup as above, except that we took the continuous outcome y , defined $p = 1/(1 + \exp(-y))$ and used this to generate a two-class outcome z with $\Pr(z = 1) = p$, $\Pr(z = 0) = 1 - p$. We compared the speed of **glmnet** to the interior point method **lllogreg** (Koh *et al.* 2007b,a), Bayesian binary regression (**BBR**, Madigan and Lewis 2007; Genkin *et al.* 2007), and the lasso penalized logistic program **LPL** supplied by Ken Lange (see Wu and Lange 2008). The latter two methods also use a coordinate descent approach.

The **BBR** software automatically performs ten-fold cross-validation when given a set of λ values. Hence we report the total time for ten-fold cross-validation for all methods using the

Table 1: Timings (in seconds) for **glmnet** and **lars** algorithms for linear regression with lasso penalty. The first line is **glmnet** using **naive** updating while the second uses **covariance** updating. Total time for 100 λ values, averaged over 3 runs.

same 100 λ values for all. Table 2 shows the results; in some cases, we omitted a method when it was seen to be very slow at smaller values for N or p . Again we see that **glmnet** is the clear winner: it slows down a little under high correlation. The computation seems to be roughly linear in N , but grows faster than linear in p . Table 3 shows some results when the feature matrix is sparse: we randomly set 95% of the feature values to zero. Again, the **glmnet** procedure is significantly faster than **l1logreg**.

Table 2: Timings (seconds) for logistic models with lasso penalty. Total time for tenfold cross-validation over a grid of 100 λ values.

5.3. Real data

Table 4 shows some timing results for four different datasets.

- Cancer ([Ramaswamy et al. 2002](#)): gene-expression data with 14 cancer classes. Here we compare **glmnet** with **BMR** ([Genkin et al. 2007](#)), a multinomial version of **BBR**.
- Leukemia ([Golub et al. 1999](#)): gene-expression data with a binary response indicating type of leukemia—*AML* vs *ALL*. We used the preprocessed data of [Dettling \(2004\)](#).
- InternetAd ([Kushmerick 1999](#)): document classification problem with mostly binary features. The response is binary, and indicates whether the document is an advertisement. Only 1.2% nonzero values in the predictor matrix.

| Logistic regression – Sparse features | | | | | | |
|---------------------------------------|--------|--------|--------|--------|--------|--------|
| Correlation | | | | | | |
| | 0 | 0.1 | 0.2 | 0.5 | 0.9 | 0.95 |

| glmnet | 10.18 | 10.35 | 9.93 | 10.04 | 9.02 | 8.91 |
| l1logreg | 130.27 | 124.88 | 124.18 | 129.84 | 137.21 | 159.54 |
| BBR | 45.72 | 47.50 | 47.46 | 48.49 | 56.29 | 60.21 |

Table 3: Timings (seconds) for logistic model with lasso penalty and sparse features (95% zero). Total time for ten-fold cross-validation over a grid of 100 λ values.

- **NewsGroup** (Lang 1995): document classification problem. We used the training set cultured from these data by Koh *et al.* (2007a). The response is binary, and indicates a subclass of topics; the predictors are binary, and indicate the presence of particular tri-gram sequences. The predictor matrix has 0.05% nonzero values.

All four datasets are available online with this publication as saved R data objects (the latter two in sparse format using the **Matrix** package, Bates and Maechler 2009).

For the **Leukemia** and **InternetAd** datasets, the **BBR** program used fewer than 100 λ values so we estimated the total time by scaling up the time for smaller number of values. The **InternetAd** and **NewsGroup** datasets are both sparse: 1% nonzero values for the former, 0.05% for the latter. Again **glmnet** is considerably faster than the competing methods.

5.4. Other comparisons

When making comparisons, one invariably leaves out someones favorite method. We left out our own **glm**path (Park and Hastie 2007b) extension of **lars** for GLMs (Park and Hastie 2007a), since it does not scale well to the size problems we consider here. Two referees of

| Name | Type | N | p | glmnet | l1logreg | BBR/BMR |
|-------------------|----------|--------|---------|---------------|-----------------|----------------|
| Dense | | | | | | |
| Cancer | 14 class | 144 | 16,063 | 2.5 mins | | 2.1 hrs |
| Leukemia | 2 class | 72 | 3571 | 2.50 | 55.0 | 450 |
| Sparse | | | | | | |
| InternetAd | 2 class | 2359 | 1430 | 5.0 | 20.9 | 34.7 |
| NewsGroup | 2 class | 11,314 | 777,811 | 2 mins | 3.5 hrs | |

Table 4: Timings (seconds, unless stated otherwise) for some real datasets. For the **Cancer**, **Leukemia** and **InternetAd** datasets, times are for ten-fold cross-validation using 100 values of λ ; for **NewsGroup** we performed a single run with 100 values of λ , with $\lambda_{\min} = 0.05\lambda_{\max}$.

| | MacBook Pro | HP Linux server |
|------------------|-------------|-----------------|
| glmnet | 0.34 | 0.13 |
| penalized | 10.31 | |
| OWL-QN | | 314.35 |

Table 5: Timings (seconds) for the **Leukemia** dataset, using 100 λ values. These timings were performed on two different platforms, which were different again from those used in the earlier timings in this paper.

an earlier draft of this paper suggested two methods of which we were not aware. We ran a single benchmark against each of these using the **Leukemia** data, fitting models at 100 values of λ in each case.

- **OWL-QN**: Orthant-Wise Limited-memory Quasi-Newton Optimizer for ℓ_1 -regularized Objectives (Andrew and Gao 2007a,b). The software is written in C++, and available from the authors upon request.
- The R package **penalized** (Goeman 2009b,a), which fits GLMs using a fast implementation of gradient ascent.

Table 5 shows these comparisons (on two different machines); **glmnet** is considerably faster in both cases.

6. Selecting the tuning parameters

The algorithms discussed in this paper compute an entire path of solutions (in λ) for any particular model, leaving the user to select a particular solution from the ensemble. One general approach is to use prediction error to guide this choice. If a user is data rich, they can set aside some fraction (say a third) of their data for this purpose. They would then evaluate the prediction performance at each value of λ , and pick the model with the best performance.

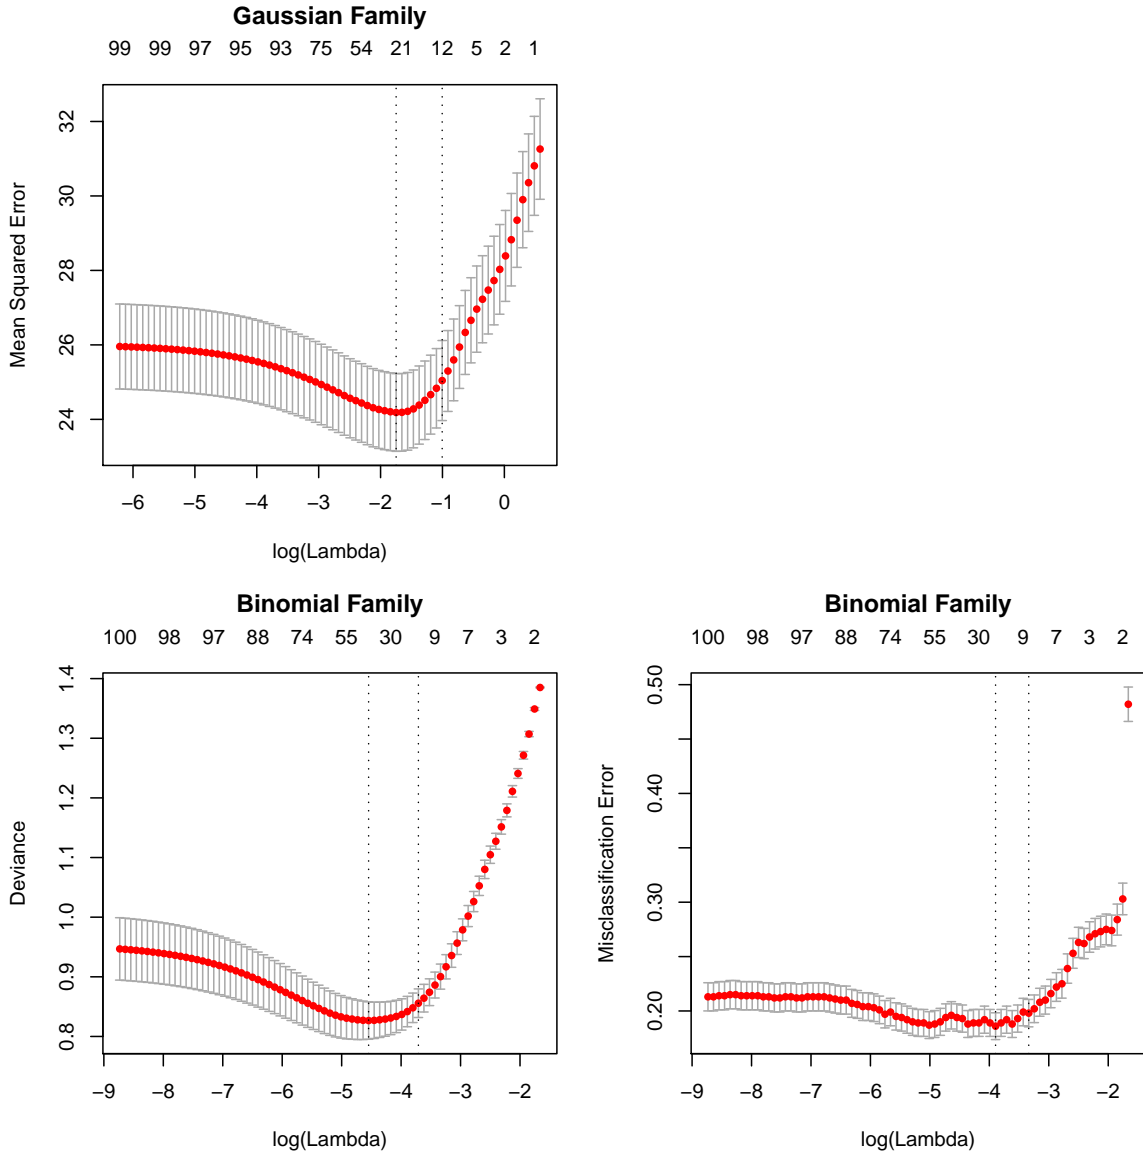

Figure 2: Ten-fold cross-validation on simulated data. The first row is for regression with a Gaussian response, the second row logistic regression with a binomial response. In both cases we have 1000 observations and 100 predictors, but the response depends on only 10 predictors. For regression we use mean-squared prediction error as the measure of risk. For logistic regression, the left panel shows the mean deviance (minus twice the log-likelihood on the left-out data), while the right panel shows misclassification error, which is a rougher measure. In all cases we show the mean cross-validated error curve, as well as a one-standard-deviation band. In each figure the left vertical line corresponds to the minimum error, while the right vertical line the largest value of lambda such that the error is within one standard-error of the minimum—the so called “one-standard-error” rule. The top of each plot is annotated with the size of the models.

Alternatively, they can use K -fold cross-validation (Hastie *et al.* 2009, for example), where the training data is used both for training and testing in an unbiased way.

Figure 2 illustrates cross-validation on a simulated dataset. For logistic regression, we sometimes use the binomial deviance rather than misclassification error, since the latter is smoother. We often use the “one-standard-error” rule when selecting the best model; this acknowledges the fact that the risk curves are estimated with error, so errs on the side of parsimony (Hastie *et al.* 2009). Cross-validation can be used to select α as well, although it is often viewed as a higher-level parameter and chosen on more subjective grounds.

7. Discussion

Cyclical coordinate descent methods are a natural approach for solving convex problems with ℓ_1 or ℓ_2 constraints, or mixtures of the two (elastic net). Each coordinate-descent step is fast, with an explicit formula for each coordinate-wise minimization. The method also exploits the sparsity of the model, spending much of its time evaluating only inner products for variables with non-zero coefficients. Its computational speed both for large N and p are quite remarkable.

An R-language package **glmnet** is available under general public licence (GPL-2) from the Comprehensive R Archive Network at <http://CRAN.R-project.org/package=glmnet>. Sparse data inputs are handled by the **Matrix** package. MATLAB functions (Jiang 2009) are available from <http://www-stat.stanford.edu/~tibs/glmnet-matlab/>.

Acknowledgments

We would like to thank Holger Hoefling for helpful discussions, and Hui Jiang for writing the MATLAB interface to our Fortran routines. We thank the associate editor, production editor and two referees who gave useful comments on an earlier draft of this article.

A. Proof of Theorem 1

We have

$$c_j = \arg \min_t \sum_{\ell=1}^K \left[\frac{1}{2}(1-\alpha)(\beta_{j\ell} - t)^2 + \alpha|\beta_{j\ell} - t| \right]. \quad (32)$$

Suppose $\alpha \in (0, 1)$. Differentiating w.r.t. t (using a sub-gradient representation), we have

$$\sum_{\ell=1}^K [-(1-\alpha)(\beta_{j\ell} - t) - \alpha s_{j\ell}] = 0 \quad (33)$$

where $s_{j\ell} = \text{sign}(\beta_{j\ell} - t)$ if $\beta_{j\ell} \neq t$ and $s_{j\ell} \in [-1, 1]$ otherwise. This gives

$$t = \bar{\beta}_j + \frac{1}{K} \frac{\alpha}{1-\alpha} \sum_{\ell=1}^K s_{j\ell} \quad (34)$$

It follows that t cannot be larger than β_j^M since then the second term above would be negative and this would imply that t is less than $\bar{\beta}_j$. Similarly t cannot be less than $\bar{\beta}_j$, since then the second term above would have to be negative, implying that t is larger than β_j^M .
